December 12, 2025

ABSTRACT

Aims. This study aims to develop "HealthTrace," a deep learning-based forecasting system designed to predict disease incidence 14 days in advance. The primary objective is to utilize Long Short-Term Memory (LSTM) networks to provide public health officials in Iloilo City with an accurate early warning system, facilitating proactive resource allocation and timely intervention.

Methods. The system was built using a comprehensive dataset from the CCHAIN project, comprising daily records of 52 environmental, socioeconomic, and health features over two years. Data processing involved normalizing these features using MinMax scaling and structuring them into 30-day temporal sequences to capture incubation periods. We implemented and compared two distinct recurrent neural network architectures—Long Short-Term Memory (LSTM) and Gated Recurrent Units (GRU)—using TensorFlow and Keras. A rigorous hyperparameter tuning process was conducted, evaluating 16 different configurations across varying learning rates, batch sizes, and optimizers (Adam, RMSprop, SGD) to identify the optimal model structure for minimizing regression error.

Results. The study revealed that the LSTM architecture utilizing the Adam optimizer (Configuration 15) yielded the highest predictive accuracy, achieving a Test R^2 score of approximately 0.52 and effectively modeling non-linear disease trends. While GRU models offered a lighter parameter footprint and faster inference times, they demonstrated slightly lower accuracy compared to the LSTM baseline. The comparative analysis highlighted a distinct hierarchy in optimizer performance, with adaptive methods (Adam) significantly outperforming Stochastic Gradient Descent (SGD). The final deployed system successfully generates 14-day forecasts with low Mean Absolute Error, providing a functional web-based dashboard for real-time monitoring and risk assessment.

1. Problem & Solution Overview

1.1. The Problem

Public health officials in Iloilo City and the Philippines face significant challenges in allocating resources for disease outbreaks such as Dengue, Typhoid, and Leptospirosis. Traditional statistical methods often fail to capture the complex, non-linear dependencies between climate factors (rainfall, humidity, temperature) and disease incubation periods, leading to delayed responses and overwhelmed healthcare facilities.

1.2. The Solution (HealthTrace)

To address this, we developed HealthTrace, a Python-based forecasting system. The core of this solution is a Deep Neural Network utilizing Long Short-Term Memory (LSTM) and Gated Recurrent Units (GRU) architectures. Unlike standard regression, these recurrent networks are capable of learning long-term temporal dependencies in time-series data, allowing us to predict disease incidence 14 days in advance based on historical climate patterns.

2. Tools, Ethics & Dataset

2.1. Tools & Technologies

- **Backend:** Flask
- **Deep Learning:** TensorFlow/Keras
- **Data Processing:** Pandas, NumPy, Scikit-learn
- **Visualization:** Plotly.js
- **Frontend:** HTML5, CSS3, JavaScript

2.2. Privacy & Bias Mitigation

The dataset consists entirely of aggregated daily counts. No Personally Identifiable Information (PII) or specific patient records were used, ensuring full compliance with user privacy standards.

We normalized all features using MinMaxScaler to prevent features with larger ranges (like Rainfall) from biasing the network weights against smaller range features (like Disease Count).

2.3. Dataset Source

The model was trained using historical climate and health data aggregated from CCHAIN (Climate Change and Health in the Philippines).

2.3.1. Input Features

The forecasting model utilizes 2 primary input feature categories: Environmental & Socioeconomic Features, and Health Features. The Environmental & Socioeconomic Features consists of nine subcategories: Climate & Precipitation, Temperature, Air Quality, Socioeconomic, Wealth Index, Vegetation, Sanitation & Water Access, Water Bodies, and Healthcare Access. These environmental and health metrics are processed into 30-day time-series sequences, allowing the LSTM network to effectively learn the incubation periods and delayed effects of climate on disease transmission. The dataset consists of approximately 11,680 total data points, representing two full years of continuous daily records across the four tracked diseases.

Table 1: Complete List of Environmental & Socioeconomic Features

| <i>Climate & Precipitation</i> | |
|--------------------------------------|--------------------------|
| precipitation | spi3 |
| spi6 | precip_anomaly |
| precipitation_7day | precipitation_30day |
| <i>Temperature</i> | |
| tmin | tmax |
| tave | temp_range |
| tave_7day | tave_30day |
| <i>Air Quality</i> | |
| no2 | co |
| so2 | o3 |
| pm10 | pm25 |
| <i>Socioeconomic</i> | |
| pop_count_total | pop_density_mean |
| avg_rad_mean | |
| <i>Wealth Index</i> | |
| rwi_mean | rwi_median |
| rwi_std | |
| <i>Vegetation</i> | |
| ndvi | |
| <i>Sanitation & Water Access</i> | |
| drinking_water_count | drinking_water_nearest |

Table 2: Target Health Variable

| Health Feature |
|----------------|
| disease_cases |

The following figures present sample time-series visualizations derived from the dengue historical dataset. These graphs illustrate the temporal dynamics and trends of four distinct feature categories:

- **Precipitation:** Daily rainfall patterns, seasonal intensity and variability.
- **Disease Cases:** Incidence of dengue, the primary epidemiological target variable.
- **SPI6:** Medium-term hydrological conditions, identifies prolonged wet or dry periods affecting vector breeding.
- **Population Count:** Demographic trend and scale of the exposed population over the study period.

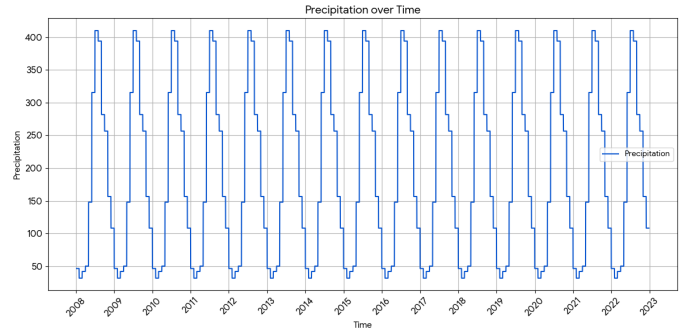

Fig. 1: Precipitation over Time

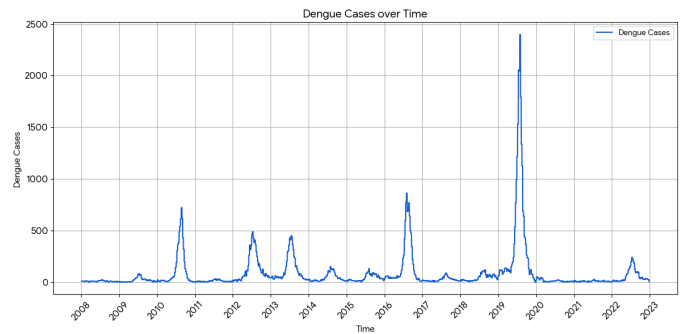

Fig. 2: Dengue Cases over Time

Fig. 3: SPI6 over Time

Fig. 4: Population Count over Time

3. Neural Network Structure

The forecasting core utilizes a sequential Deep Learning architecture designed for time-series regression. The model consists of two stacked recurrent layers—either Long Short-Term Memory (LSTM) or Gated Recurrent Units (GRU)—to capture temporal dependencies in the disease data. The first layer contains 64 units and returns sequences to retain temporal structure, while the second layer reduces complexity with 32 units. To prevent overfitting, Dropout regularization (rate of 0.3) is applied after each recurrent layer. The architecture concludes with a fully connected Dense layer of 32 units using ReLU activation for non-linear feature processing, followed by a single-unit output layer that predicts the specific number of disease cases.

Table 3: Neural Network Architecture

| Layer | Type | Units/Rate | Activation | Configuration / Purpose |
|--|------------|------------|------------|--------------------------------------|
| <i>Recurrent Layers (Feature Extraction)</i> | | | | |
| 1 | Input | 52 | – | Seq Length=30, Features=52 |
| 2 | LSTM / GRU | 64 | Tanh | Return Sequences=True |
| 3 | Dropout | 0.2 | – | Regularization (Prevent Overfitting) |
| 4 | LSTM / GRU | 32 | Tanh | Return Sequences=False |
| 5 | Dropout | 0.3 | – | Regularization (Prevent Overfitting) |
| <i>Dense Layers (Prediction)</i> | | | | |
| 6 | Dense | 32 | ReLU | Feature Interpretation |
| 7 | Dropout | 0.3 | – | Regularization (Prevent Overfitting) |
| 8 | Output | 1 | Linear | Final Regression Prediction |

Note: Both LSTM and GRU architectures were implemented to conduct a direct performance comparison and identify the optimal model for this specific dataset. While GRU models generally offer a lighter parameter footprint and faster inference times, the comprehensive evaluation metrics demonstrated that the LSTM architecture provided superior predictive accuracy for these disease outbreak patterns, leading to its selection as the primary model.

4. Hyperparameter Tuning

To optimize the performance of the HealthTrace forecasting system, we conducted a comprehensive series of controlled experiments. Logging for the hyperparameter tuning configurations was performed on the Dengue dataset. We evaluated a total of 16 different training configurations, systematically varying hyperparameters such as the optimizer, learning rate, batch size, units, dropout rate, and optimizer-specific parameters. The goal was to balance model complexity with generalization capabilities to avoid both underfitting and overfitting. Below are the detailed results for all 16 configurations. As shown in the results, Configuration 15 achieved the best performance on the validation set, demonstrating the highest $Test_R^2$.

4.1. Hyperparameter Tuning

4.2. Best Configuration

The figure 9 visualizes the high-dimensional relationship between the model's hyperparameters—specifically Learning Rate, Batch Size, Units, and Dropout—and its final performance metric (Test R^2). Each line represents a single training run, color-coded to indicate success: red lines denote poor performance, while green lines indicate high accuracy.

Figure 6 provides a comparative analysis of model accuracy (y-axis, Test R^2) against computational cost (x-axis, Training Time in seconds). Each data point represents a trained model configuration, with the size of the marker corresponding to the model's complexity (number of LSTM units).

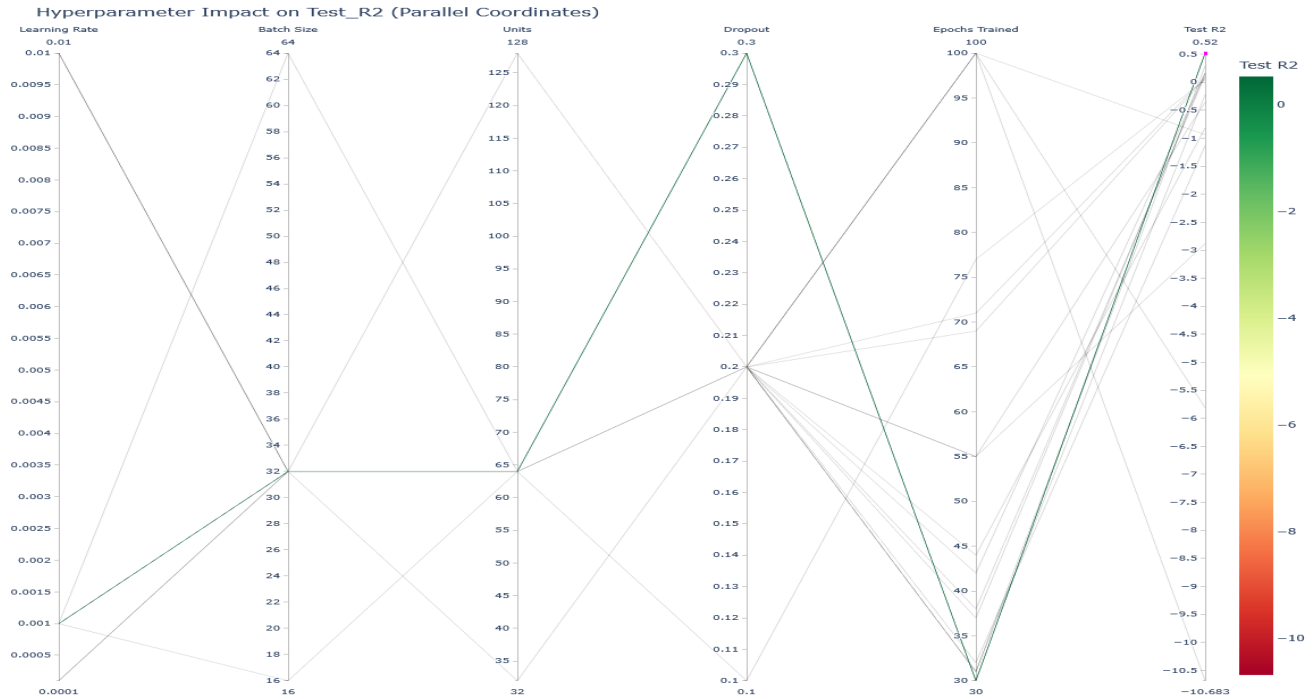

Fig. 5: Hyperparameter Parallel Coordinates

By tracing the path of the "best" line (configuration 15 [18]), we can observe the specific combination of settings that maximized the R^2 score. This visualization is critical for identifying stability patterns, such as whether high dropout rates consistently degrade performance or if larger unit counts are necessary for capturing complex temporal dependencies in the Dengue dataset.

Fig. 6: Hyperparameter Parallel Coordinates

The gold star explicitly marks configuration 15 [18], identifying it as the optimal trade-off between performance and efficiency. Importantly, the color-coding reveals a distinct hierarchy in optimizer performance: the Adam optimizer consistently achieved the top results and was used by the best model, followed by RMSprop in second place. In contrast, SGD (Stochastic Gradient Descent) produced the lowest R^2 scores, demonstrating that adaptive learning rate methods are significantly more effective for this specific forecasting task.

5. System Implementation Results

The HealthTrace application visualizes complex epidemiological data through three primary components, designed to provide actionable insights for health officials.

5.1. Forecast Analysis Graph

This component serves as the primary visualization for the disease outbreak timeline, bridging historical data with future predictions.

- Historical Context: Displays the confirmed disease cases from the preceding 30 days, providing a baseline for the current epidemiological trend.
- Predictive Model Output: Projects the expected number of cases for the next 14 days.

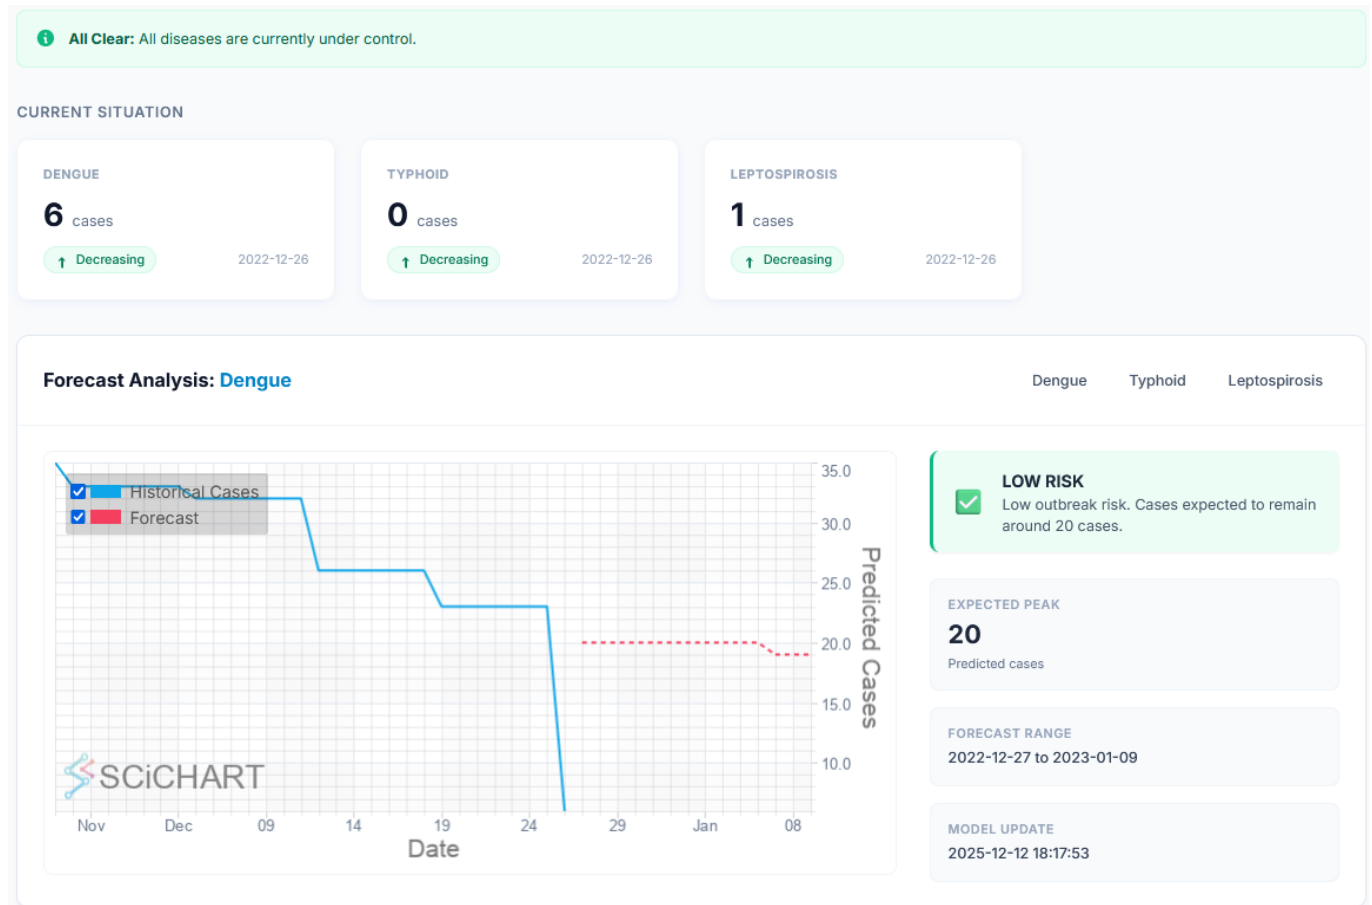

Fig. 7: Forecast Analysis

5.2. Feature Impact Analysis

Understand which environmental factors are driving the model's prediction for this specific timeframe. This module breaks down the "black box" of the AI model by quantifying the relationship between external variables and disease transmission.

- Uses horizontal bar charts to represent the correlation strength (Impact %) of various features.
- Features are organized into distinct categories for readability, including Climate & Precipitation, Socioeconomic Factors, Air Quality, and Sanitation & Water Access.

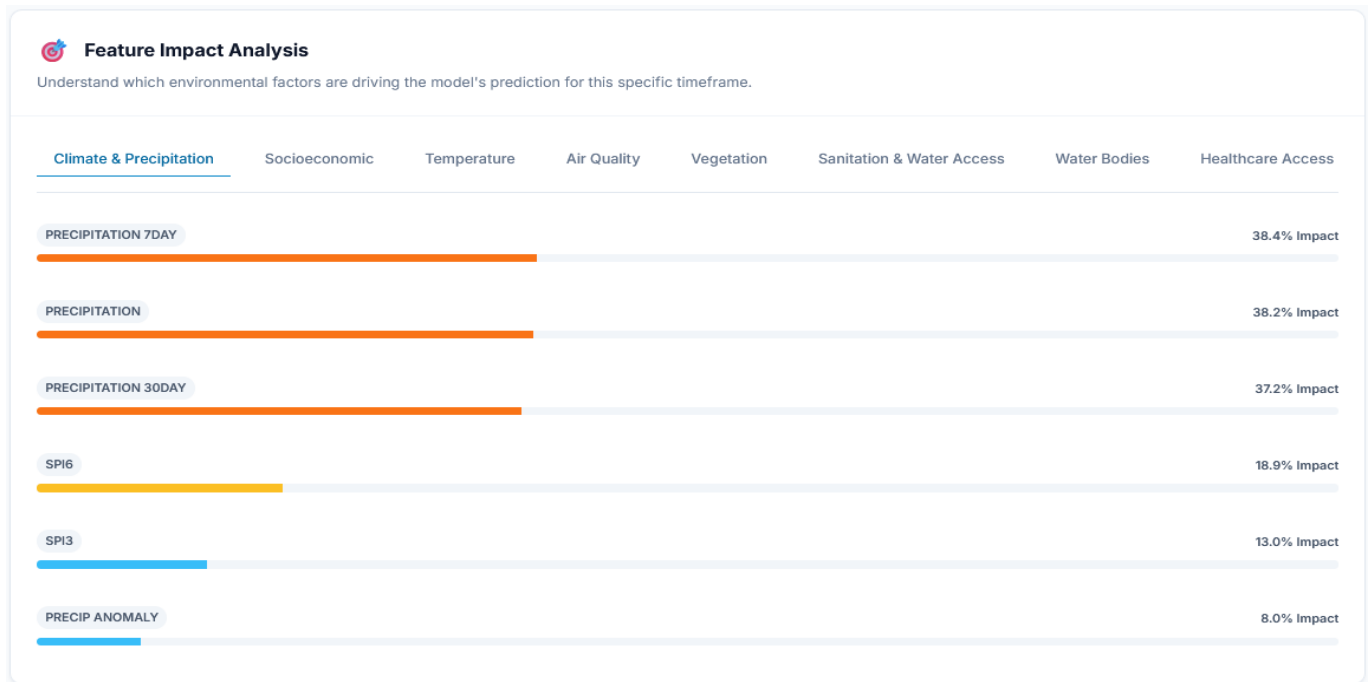

Fig. 8: Feature Impact

5.3. Forecast Data

While the graphs provide trends, this section provides the concrete numerical data required for resource allocation and reporting.

- Forecast Table: A tabular view listing the specific date and the exact number of predicted cases (rounded to the nearest integer) for the entire 14-day forecast window.

Fig. 9: Forecast Data

6. Conclusion

This study successfully established "HealthTrace," a functional deep learning application capable of forecasting disease outbreaks in Iloilo City up to 14 days in advance. By integrating 52 distinct environmental and socioeconomic features—ranging from precipitation anomalies to healthcare access indices—we demonstrated that deep learning models can effectively capture the complex, non-linear dependencies between climate patterns and disease incidence.

Our rigorous hyperparameter tuning process identified that a 2-layer LSTM architecture with 64 units and a dropout rate of 0.3, optimized via Adam, provided the most robust generalization (Configuration 15), achieving a Test R^2 of 0.52. The comparative analysis conclusively showed that while GRU architectures offer computational efficiency, the LSTM's ability to retain long-term dependencies proved superior for this specific time-series regression task. Furthermore, the poor performance of the SGD optimizer underscores the necessity of adaptive learning rate methods for high-dimensional health data.

The deployed web application bridges the gap between complex data science and public health utility, offering officials a clear, interactive dashboard for proactive decision-making. Future enhancements will focus on integrating real-time data feeds from local health authorities, exploring ensemble modeling techniques to further improve accuracy, and expanding the system to support multi-region forecasting.
